LAPLACIANS ON THE BASILICA JULIA SET

LUKE G. ROGERS AND ALEXANDER TEPLYAEV

Abstract. We consider the basilica Julia set of the polynomial $P(z) = z^2 - 1$ and construct all possible resistance (Dirichlet) forms, and the corresponding Laplacians, for which the topology in the effective resistance metric coincides with the usual topology. Then we concentrate on two particular cases. One is a self-similar harmonic structure, for which the energy renormalization factor is 2, the spectral dimension is $\log 9/\log 6$, and we can compute all the eigenvalues and eigenfunctions by a spectral decimation method. The other is graph-directed self-similar under the map $z \mapsto P(z)$; it has energy renormalization factor $\sqrt{2}$ and spectral dimension $4/3$, but the exact computation of the spectrum is difficult. The latter Dirichlet form and Laplacian are in a sense conformally invariant on the basilica Julia set.

1. Introduction

In the rapidly developing theory of analysis on fractals, the principal examples are finitely ramified self-similar fractal sets that arise as fixed points of iterated function systems (IFS). For example, the recent book of Strichartz [22] gives a detailed account of the rich structure that has been developed for studying differential equations on the the well known Sierpinski Gasket

fractal, primarily by using the methods of Kigami (see [11]). Some generalizations exist to fractals generated by graph-directed IFS and certain random IFS constructions [7, 9, 8], but it is desirable to extend the methods to other interesting cases. Among the most important and rich collections of fractals are the Julia sets of complex dynamical systems (see, for instance, [3, 4, 16]). In this paper we construct Dirichlet forms and Laplacians on the Julia set of the quadratic polynomial $P(z) = z^2 - 1$, which is often referred to as the basilica Julia set, see Figure 1. The basilica Julia set is particularly interesting because it is one of the simplest examples of a Julia set with nontrivial topology, and analyzing it in detail shows how to transfer the differential equation methods of [22] to more general Julia sets.

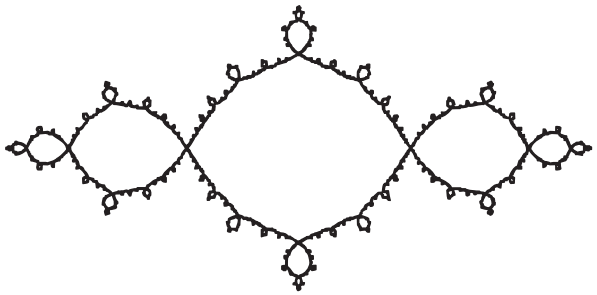

FIGURE 1. The basilica Julia set, the Julia set of $z^2 - 1$.

Another reason for our interest in the basilica Julia set comes from its appearance as the limit set of the so-called basilica self-similar group. This class of groups came to prominence because of their relation to finite automata and groups of intermediate growth, first discovered by Grigorchuk. The reader can find extensive background on self-similar groups in the monograph of Nekrashevych [17], some interesting calculations particularly relevant to the basilica group in [10], and a review of the most recent developments in [18].

Since local regular Dirichlet forms and their Laplacians are in one-to-one correspondence, up to a natural equivalence, with symmetric continuous diffusion processes and their generators, our analysis allows the construction of diffusion processes on the basilica Julia set. Random processes of this type are interesting because they provide concrete examples of diffusions with nonstandard behavior, such as sub-Gaussian transition probabilities estimates. For a detailed study of diffusions on some finitely ramified self-similar fractals see [2] and references therein. The background on Dirichlet forms and Markov processes can be found in [6].

Our construction starts with providing the basilica Julia set with a finitely ramified cell structure, (Definition 2.1 in Section 2). According to [23], such a cell structure makes it possible to use abstract results of Kigami [12] (see also [13]) to construct local regular Dirichlet forms that yield a topology equivalent to that induced from $\mathbb{C}$. In Section 3 we describe all such Dirichlet forms, and in Section 4 we describe Laplacians corresponding to these forms and arbitrary

Radon measures. Among these Laplacians, some seem more interesting than others. For example, there is a family of Laplacians with sufficient symmetry that their graph approximations admit a spectral decimation like that in [1, 5, 20, 21]; this allows us to describe the eigenvalues and eigenfunctions fairly explicitly in Section 5. The energy renormalization factor is 2 and the spectral dimension is $\log 9/\log 6$ in this case.

In Section 6 we describe the unique, up to a scalar multiple, Dirichlet form and Laplacian that are conformally invariant under the dynamical system. The latter Laplacian does not have spectral decimation and we cannot determine its eigenstructure, but its spectral dimension can be computed to be $4/3$ using the renewal theorem in [9]. The energy renormalization factor is $\sqrt{2}$ in the conformally invariant case. One can find related group-theoretic computations and discussions in [18].

2. A finitely ramified cell structure on the basilica Julia set

We will construct Dirichlet forms and Laplacians on the basilica Julia set as limits of the corresponding objects on a sequence of approximating graphs. In order that we may later compare the natural topology associated with the Dirichlet form with the induced topology from $\mathbb{C}$, we will require some structure on these approximations. The ideas we need are from [12, 23], in particular the following definition is almost identical to that in [23]. The only change is that we will not need the existence of harmonic coordinates, and therefore do not need to assume that each V_α has at least two elements.

Definition 2.1. A *finitely ramified set* F is a compact metric space with a *cell structure* $\mathcal{F} = \{F_\alpha\}_{\alpha\in\mathcal{A}}$ and a *boundary (vertex) structure* $\mathcal{V} = \{V_\alpha\}_{\alpha\in\mathcal{A}}$ such that the following conditions hold.

(FRCS1) $\mathcal{A}$ is a countable index set;
(FRCS2) each F_α is a distinct compact connected subset of F;
(FRCS3) each V_α is a finite subset of F_α;
(FRCS4) if $F_\alpha = \bigcup_{j=1}^k F_{\alpha_j}$ then $V_\alpha \subset \bigcup_{j=1}^k V_{\alpha_j}$;
(FRCS5) there exists a filtration $\{\mathcal{A}_n\}_{n=0}^\infty$ such that
  (i) $\mathcal{A}_n$ are finite subsets of $\mathcal{A}$, $\mathcal{A}_0 = \{0\}$, and $F_0 = F$;
  (ii) $\mathcal{A}_n \cap \mathcal{A}_m = \varnothing$ if $n \neq m$;
  (iii) for any $\alpha \in \mathcal{A}_n$ there are $\alpha_1, ..., \alpha_k \in \mathcal{A}_{n+1}$ such that $F_\alpha = \bigcup_{j=1}^k F_{\alpha_j}$;
(FRCS6) $F_{\alpha'} \bigcap F_\alpha = V_{\alpha'} \bigcap V_\alpha$ for any two distinct $\alpha, \alpha' \in \mathcal{A}_n$;
(FRCS7) for any strictly decreasing infinite cell sequence $F_{\alpha_1} \supsetneq F_{\alpha_2} \supsetneq ...$ there exists $x \in F$ such that $\bigcap_{n\geqslant 1} F_{\alpha_n} = \{x\}$.

If these conditions are satisfied, then

$$(F, \mathcal{F}, \mathcal{V}) = (F, \{F_\alpha\}_{\alpha\in\mathcal{A}}, \{V_\alpha\}_{\alpha\in\mathcal{A}})$$

is called a *finitely ramified cell structure.*

Notation 2.2. We denote $V_n = \bigcup_{\alpha\in\mathcal{A}_n} V_\alpha$. Note that $V_n \subset V_{n+1}$ for all $n \geqslant 0$ by Definition 2.1. We say that F_α is an n-cell if $\alpha \in \mathcal{A}_n$.

In this definition the vertex boundary V_0 of $F_0 = F$ can be arbitrary, and in general may have no relation with the topological structure of F. However the cell structure is intimately connected to the topology, as the following result shows.

Proposition 2.3 ([23])**.** *The following are true of a finitely ramified cell structure.*

1. *For any $x \in F$ there is a strictly decreasing infinite sequence of cells satisfying condition (FRCS7) of the definition. The diameter of cells in any such sequence tend to zero.*
2. *The topological boundary of F_α is contained in V_α for any $\alpha \in \mathcal{A}$.*
3. *The set $V_* = \bigcup_{\alpha\in\mathcal{A}} V_\alpha$ is countably infinite, and F is uncountable.*
4. *For any distinct $x, y \in F$ there is $n(x, y)$ such that if $m \geqslant n(x, y)$ then any m-cell can not contain both x and y.*
5. *For any $x \in F$ and $n \geqslant 0$, let $U_n(x)$ denote the union of all n-cells that contain x. Then the collection of open sets $\mathcal{U} = \{U_n(x)^\circ\}_{x\in F,n\geqslant 0}$ is a fundamental sequence of neighborhoods. Here B° denotes the topological interior of a set B. Moreover, for any $x \in F$ and open neighborhood U of x there exist $y \in V_*$ and n such that $x \in U_n(x) \subset U_n(y) \subset U$. In particular, the smaller collection of open sets $\mathcal{U}' = \{U_n(x)^\circ\}_{x\in V_*,n\geqslant 0}$ is a countable fundamental sequence of neighborhoods.*

In general a finitely ramified fractal may have many filtrations, and the Dirichlet forms, resistance forms and energy measures we will discuss later are independent of the filtration. However it is natural in the context of a self-similar set to consider a filtration that is adapted to the self-similarity. We now define a finitely ramified cell structure and a filtration, which have certain self-similarity properties, on the basilica Julia set.

By definition, the 0-cell is the basilica Julia set fractal, which we denote by J. Let us write $a = \frac{1-\sqrt{5}}{2}$ for one of the fixed points of $z^2 - 1$. The interiors of four 1-cells are obtained by removing the points $\pm a$; this disconnects the part of J surrounding the basin around 0 into symmetric upper and lower pieces, and separates these from two symmetric arms, one on the left and one on the right, see Figure 2 (and also Figure 5). The top and bottom cells we denote $J_{(1)}$ and $J_{(2)}$ respectively, and the left and right cells we denote $J_{(3)}$ and $J_{(4)}$ respectively. The cells $J_{(1)}$ and $J_{(2)}$ each have two boundary points, while $J_{(3)}$ and $J_{(4)}$ each have one boundary point. In the notation of Definition 2.1,

$$V_{(1)} = V_{(2)} = \{\pm a\}, \quad V_{(3)} = \{-a\}, \quad V_{(4)} = \{a\}$$

and therefore the boundary set of the fractal is $V_0 = \{-a, a\}$. Note that the other fixed point, $b = \frac{1+\sqrt{5}}{2}$, does not play any role in defining the cell structure.

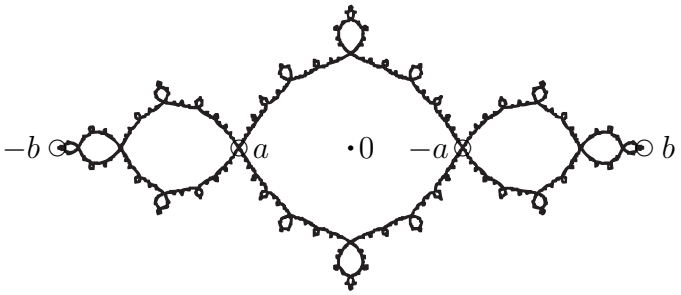

FIGURE 2. The the Julia set of $z^2 - 1$ with the repulsive fixed points $a = \frac{1-\sqrt{5}}{2}$ and $b = \frac{1+\sqrt{5}}{2}$ circled.

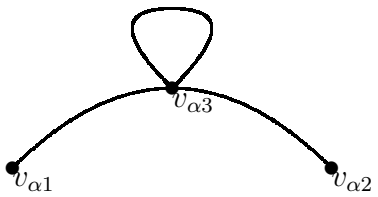

FIGURE 3. An arc-type cell

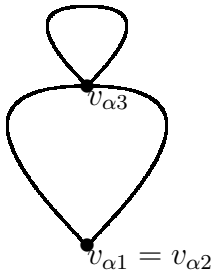

FIGURE 4. A loop-type cell

For $n \geq 1$ we set $\mathcal{A}_n = \{1, 2, 3, 4\} \times \{1, 2, 3\}^{n-1}$. To define the smaller cells, we introduce the following definition. If a cell has two boundary points, it is called an *arc-type cell*. If a cell has one boundary point, it is called a *loop-type cell*.

Each arc-type n-cell J_α is a union of three $n+1$-cells $J_{\alpha 1}$, $J_{\alpha 2}$ and $J_{\alpha 3}$; $J_{\alpha 1}$ and $J_{\alpha 2}$ are arc-type cells connected at a middle point, while $J_{\alpha 3}$ is a loop-type cell attached at the same point (Figure 3).

Each loop-type n-cell J_α is a union of three $n+1$-cells, $J_{\alpha 1}$, $J_{\alpha 2}$ and $J_{\alpha 3}$; $J_{\alpha 1}$ and $J_{\alpha 2}$ are arc-type cells connected at two points, one of which is the unique boundary point $v_\alpha \in V_{(\alpha)}$, while the other is the boundary point of the loop-type cell $J_{\alpha 3}$ (Figure 4).

The existence of this decomposition is a consequence of known results on the topology of quadratic Julia sets. In essence we have used the fact that the filled Julia set is the closure of the union of countably many closed topological discs, and that the intersections of these discs are points that are dense in J and pre-periodic for the dynamics. The Julia set itself consists of the closure of

the union of the boundaries of these topological discs. This structure occurs for the Julia set of every quadratic polynomial $z^2 + c$ for which c is in the interior of a hyperbolic component of the Mandelbrot set or is the intersection point of two hyperbolic components, so in particular for the basilica Julia set because $c = -1$ lies within the period 2 component. Details may be found in [3, 4, 16]. These general results imply that a FRCS may be obtained for all quadratic Julia sets with suitable c values in the manner similar to that described above, however the basilica Julia set is a sufficiently simple case that the reader may prefer to verify directly that the existence (see, for instance, [16, Theorem 18.11]) of internal and external rays landing at a implies that deletion of $\pm a$ decomposes J into the four components $J_{(i)}$, $i = 1, 2, 3, 4$, while the remainder of the decomposition follows by examining the inverse images of these sets under the dynamics.

Definition 2.4. The basilica self-similar sequence of graphs G_n have vertices V_n as previously described. There is one edge for each pair of vertices joined by an arc-type n-cell, as well as one loop at each vertex at which there is a loop-type n-cell. The result is shown in Figure 5, and we emphasize that it is highly dependent on our choice of filtration.

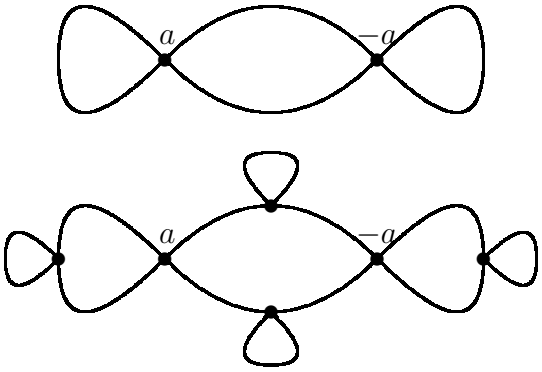

FIGURE 5. Basilica self-similar sequence of graphs: graphs G_0 and G_1.

The sequence of graphs in Figure 5 is well adapted to the construction of the Kigami resistance forms, and hence the Dirichlet forms, on J. For this reason it plays a prominent role in Section 3. In Section 5 a spectral decimation method for this sequence of graphs is used to obtain a full description of the corresponding Laplacian.

It should be noted, however, that this is not the only sequence of graphs that we will consider. A sequence that is arguably more natural, is the conformally invariant graph-directed sequence of graphs for the basilica Julia set, shown in Figure 6.

These graphs will be considered in Section 6, where detailed definitions can be found. Their construction is related to group-theoretic results [17,

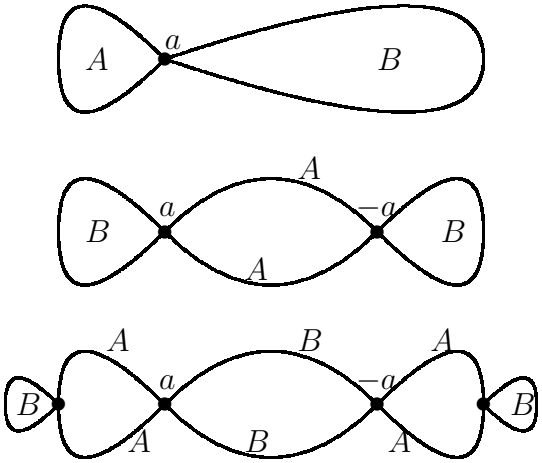

FIGURE 6. Basilica conformally invariant graph-directed sequence of graphs.

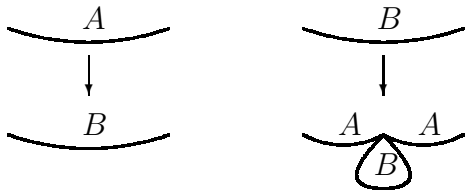

FIGURE 7. The substitution scheme for the basilica conformally invariant graph-directed sequence of graphs.

18, and references therein], and in particular to the substitution scheme in Figure 7. The cell structure and the filtration could be defined starting with the single point boundary set $\{a\}$, and then taking the inverse images $P^{-n}\{a\}$ of this point under the polynomial $P(z)$, which is of course different from V_n in Definition 2.4. More precisely, for any n and k we have $V_n \neq P^{-k}\{a\}$, even though $V_* = \bigcup_{n\geq 0} V_n = \bigcup_{n\geq 0} P^{-n}\{a\}$.

3. Kigami's resistance forms forms on the basilica Julia set and the local resistance metric

One way of constructing Dirichlet forms on a fractal is to take limits of resistance forms on an approximating sequence of graphs. We recall the definition from [11], as well as the principal results we will require.

Definition 3.1. A pair $(\mathcal{E}, \operatorname{Dom}\mathcal{E})$ is called a resistance form on a countable set V_* if it satisfies the following conditions.

(RF1) $\operatorname{Dom}\mathcal{E}$ is a linear subspace of $\ell(V_*)$ containing constants, $\mathcal{E}$ is a non-negative symmetric quadratic form on $\operatorname{Dom}\mathcal{E}$, and $\mathcal{E}(u,u) = 0$ if and only if u is constant on V_*.

(RF2) Let $\sim$ be the equivalence relation on $\operatorname{Dom}\mathcal{E}$ defined by $u \sim v$ if and only if $u - v$ is constant on V_*. Then $(\mathcal{E}/\!\sim, \operatorname{Dom}\mathcal{E})$ is a Hilbert space.

(RF3) For any finite subset $V \subset V_*$ and for any $v \in \ell(V)$ there exists $u \in \operatorname{Dom}\mathcal{E}$ such that $u\big|_V = v$.

(RF4) For any $x, y \in V_*$ the resistance between x and y is defined to be

$$R(x,y) = \sup\left\{ \frac{\big(u(x)-u(y)\big)^2}{\mathcal{E}(u,u)} : u \in \operatorname{Dom}\mathcal{E}, \mathcal{E}(u,u) > 0 \right\} < \infty.$$

(RF5) For any $u \in \operatorname{Dom}\mathcal{E}$ we have the $\mathcal{E}(\bar{u},\bar{u}) \leqslant \mathcal{E}(u,u)$, where

$$\bar{u}(x) = \begin{cases} 1 & \text{if } u(x) \geqslant 1, \\ u(x) & \text{if } 0 < u(x) < 1, \\ 0 & \text{if } u(x) \leqslant 1. \end{cases}$$

Property (RF5) is called the Markov property.

Proposition 3.2 (Kigami, [12]). *Resistance forms have the following properties.*

(1) *The effective resistance R is a metric on V_*. Any function in $\operatorname{Dom}\mathcal{E}$ is R-continuous; in particular, if Ω is the R-completion of V_* then any $u \in \operatorname{Dom}\mathcal{E}$ has a unique R-continuous extension to Ω.*

(2) *For any finite subset $U \subset V_*$, a finite dimensional Dirichlet form $\mathcal{E}_U$ on U may be defined by*

$$\mathcal{E}_U(f,f) = \inf\{\mathcal{E}(g,g) : g \in \operatorname{Dom}\mathcal{E}, g\big|_U = f\}.$$

There is a unique g at which the infimum is achieved. The form $\mathcal{E}_U$ is called the trace of $\mathcal{E}$ on U, and may be written $\mathcal{E}_U = \operatorname{Trace}_U(\mathcal{E})$. If $U_1 \subset U_2$ then $\mathcal{E}_{U_1} = \operatorname{Trace}_{U_1}(\mathcal{E}_{U_2})$.

Our description of the Dirichlet forms on the basilica Julia set relies on the following theorems.

Theorem 3.3 (Kigami, [12]). *Suppose that V_n are finite subsets of V_* and that $\bigcup_{n=0}^{\infty} V_n$ is R-dense in V_*. Then*

$$\mathcal{E}(f,f) = \lim_{n\to\infty} \mathcal{E}_{V_n}(f,f)$$

for any $f \in \operatorname{Dom}\mathcal{E}$, where the limit is actually non-decreasing. Is particular, $\mathcal{E}$ is uniquely defined by the sequence of its finite dimensional traces $\mathcal{E}_{V_n}$ on V_n.

Theorem 3.4 (Kigami, [12]). *Suppose that V_n are finite sets, for each n there is a resistance form $\mathcal{E}_{V_n}$ on V_n, and this sequence of finite dimensional forms is compatible in the sense that each $\mathcal{E}_{V_n}$ is the trace of $\mathcal{E}_{V_{n+1}}$ on V_n, where $n = 0, 1, 2, \ldots$. Then there exists a resistance form $\mathcal{E}$ on $V_* = \bigcup_{n=0}^{\infty} V_n$ such that*

$$\mathcal{E}(f,f) = \lim_{n\to\infty} \mathcal{E}_{V_n}(f,f)$$

for any $f \in \operatorname{Dom}\mathcal{E}$, and the limit is actually non-decreasing.

For convenience we will write $\mathcal{E}_n(f,f) = \mathcal{E}_{V_n}(f,f)$. A function is called harmonic if it minimizes the energy for the given set of boundary values, so a harmonic function is uniquely defined by its restriction to V_0. It is shown in [12] that any function h_0 on V_0 has a unique continuation to a harmonic function h, and $\mathcal{E}(h,h) = \mathcal{E}_n(h,h)$ for all n. This latter is also a sufficient condition: if $g \in \operatorname{Dom}\mathcal{E}$ then $\mathcal{E}_0(g,g) \leqslant \mathcal{E}(g,g)$ with equality precisely when g is harmonic.

For any function f on V_n there is a unique energy minimizer h among those functions equal to f on V_n. Such energy minimizers are called n-harmonic functions. As with harmonic functions, for any function $g \in \operatorname{Dom}\mathcal{E}$ we have $\mathcal{E}_n(g,g) \leqslant \mathcal{E}(g,g)$, and h is n-harmonic if and only if $\mathcal{E}_n(h,h) = \mathcal{E}(h,h)$.

It is proved in [23] that if all n-harmonic functions are continuous in the topology of F then any F-continuous function is R-continuous and any R-Cauchy sequence converges in the topology of F. In such a case there is also a continuous injection $\theta : \Omega \to F$ which is the identity on V_*, so we can identify Ω with the the R-closure of V_* in F. In a sense, Ω is the set where the Dirichlet form $\mathcal{E}$ "lives".

Theorem 3.5 ([12, 23])**.** *Suppose that all n-harmonic functions are continuous. Then $\mathcal{E}$ is a local regular Dirichlet form on $L^2(\Omega,\gamma)$, where γ is any finite Borel measure on (F,R) with the property that all nonempty open sets have positive measure.*

Proof. The regularity of $\mathcal{E}$ follows from [12, Theorem 8.10], and its locality from [23, Theorem 3]. Note that, according to [12, Theorem 8.10], in general for resistance forms one can consider σ-finite Radon measures γ. However for a compact set a Radon measure must be finite. □

The trace of $\mathcal{E}$ to the finite set V_n may be written in the form

$$\mathcal{E}_n(f,f) = \sum_{\alpha\in\mathcal{A}_n} r_\alpha^{-1}\big(f(v_{\alpha 1}) - f(v_{\alpha 2})\big)^2, \tag{3.1}$$

from which we define the resistance across J_α to be the value r_α. Note that it is not the same as $R(v_{\alpha 1}, v_{\alpha 2})$.

The values r_α may be used to define a geodesic metric that is comparable to the resistance metric. A *path* from x to y in Ω consists of a doubly infinite sequence of vertices $\{v_{\alpha_j}\}_{-\infty}^{\infty}$ and arc-type cells J_j connecting v_{α_j} to $v_{\alpha_{j+1}}$, with $\lim_{j\to-\infty} v_{\alpha_j} = x$ and $\lim_{j\to\infty} v_{\alpha_j} = y$, the limit being in the R-topology. The length of the path is the sum of the resistances of the constituent cells. If x (or y) is in V_* we permit that the sequence begins with infinite repetition of x (respectively ends with repetition of y) which are considered connected by the null cell of resistance zero, but otherwise the v_{α_j} are distinct. Let $S(x,y)$ denote the infimum of the lengths of paths from x to y; it is easy to see from the finitely ramified cell structure that there is a geodesic path that has length $S(x,y)$.

Definition 3.6. We call the geodesic metric $S(x,y)$ the local resistance metric.

Lemma 3.7. *For x and y in Ω,*

$$\frac{1}{2}S(x,y) \leq R(x,y) \leq S(x,y).$$

Proof. First consider the special case in which x and y are both in a loop-type cell J_α, and neither is contained in any smaller loop-type cell. In this case none of the smaller loop-type cells affects $R(x,y)$ or $S(x,y)$, so we may replace each such loop by its boundary vertex. The result is to reduce the loop-type cell to a topological circle. Deleting x and y from this circle leaves two resistors, one with resistance $S(x,y)$ and the other with resistance at least $S(x,y)$. The resistance $R(x,y)$ is the parallel sum of these, so satisfies $\frac{1}{2}S(x,y) \leq R(x,y) \leq S(x,y)$. This case also applies if both x and y are in $J_{(1)} \cup J_{(2)}$ and neither is in any loop-type cell.

To complete the proof we show that the resistance from x to y decomposes as a series of loop-type cells of the above form. Consider the (possibly empty) collection of loop-type cells that contain x but not y, and order them by inclusion, beginning with the largest. Let $v_{\alpha_0}, v_{\alpha_1}, v_{\alpha_2} \dots$ be the boundary vertices of these loops, and observe that $v_{\alpha_j} \to x$. Do the same for the loop-type cells containing y but not x, labeling the vertices $v_{\alpha_{-1}}, v_{\alpha_{-2}}, \dots$. If x is in V_* then the sequence will terminate with an infinite repetition of x, and similarly for y. Notice that deleting any of the v_{α_j} disconnects $v_{\alpha_{j-1}}$ from $v_{\alpha_{j+1}}$. This implies both that that the effective resistances $R(v_{\alpha_j}, v_{\alpha_{j+1}})$ sum in series to give the effective resistance $R(x,y)$, and that the resistances $S(v_{\alpha_j}, v_{\alpha_{j+1}})$ sum to $S(x,y)$. However each of the configurations $v_{\alpha_j}, v_{\alpha_{j+1}}$ is of the form of the special case given above, so satisfies

$$\frac{1}{2}S(v_{\alpha_j}, v_{\alpha_{j+1}}) \leq R(v_{\alpha_j}, v_{\alpha_{j+1}}) \leq S(v_{\alpha_j}, v_{\alpha_{j+1}}).$$

Summing over j then gives the desired inequality. □

By virtue of Theorem 3.3 and (3.1) it is apparent that we may describe a resistance form on V_* in terms of the values r_α. The simple structure of the graphs makes it easy to describe the choices of $\{r_\alpha\}_\alpha$ that give a resistance form.

Lemma 3.8. *Defining resistance forms on each V_n by* (3.1) *produces a sequence $\mathcal{E}_n$ that is compatible in the sense of Theorem 3.4 if and only if for each arc-type cell J_α,*

$$r_\alpha = r_{\alpha 1} + r_{\alpha 2}.$$

Proof. Resistance forms satisfy the well-known Kirchoff laws from electrical network theory (see [11], Section 2.1). If J_α is an arc-type cell then $J_{\alpha 1}$ and $J_{\alpha 2}$ connect $v_{\alpha 1}$ and $v_{\alpha 2}$ in series. The resistance in $V_{|\alpha+1|}$ between $v_{\alpha 1}$ and $v_{\alpha 2}$ neglecting $J \setminus J_\alpha$ is then $r_{\alpha 1} + r_{\alpha 2}$, so is compatible with the resistance across J_α in $V_{|\alpha|}$ if and only if $r_\alpha = r_{\alpha 1} + r_{\alpha 2}$. In the alternative circumstance where

J_α is a loop-type cell, there is only one boundary vertex, so r_α is not defined and no constraint on $r_{\alpha 1}$ and $r_{\alpha 2}$ is necessary. □

According to Lemma 3.8 and Theorem 3.4, one may construct a resistance form on V_* simply by choosing appropriate values r_α. It is helpful to think of choosing these values inductively, so that at the n-th stage one has the values r_α with $|\alpha| = n$. In this case there are two types of operation involved in passing to the $(n+1)$-th stage. For arc-type cells J_α with $|\alpha| = n$ one chooses $r_{\alpha 1}$ and $r_{\alpha 2}$ so they sum to r_α. For loop-type cells J_α one chooses $r_{\alpha 1}$ and $r_{\alpha 2}$ freely.

This method provides a resistance form on V_* and its R-completion Ω, but our goal is to describe Dirichlet forms on the fractal J. In order that $\Omega = J$, or equivalently that the topology from $\mathbb{C}$ coincides with the R-topology on V_*, we must further restrict the values of r_α. In the theorem below, $S-\mathrm{Diam}\big(O\big)$ denotes the diameter of a set O with respect to the local resistance metric $S(x,y)$.

Theorem 3.9. *The local regular resistance forms on V_* for which $\Omega = J$ and the R-topology is the same as the induced $\mathbb{C}$-topology are in one-to-one correspondence with the families of positive numbers r_α, one for each arc-type cell J_α, that satisfy the conditions*

$$r_\alpha = r_{\alpha 1} + r_{\alpha 2} \tag{3.2}$$

$$\lim_{n\to\infty} \max_{\alpha\in\mathcal{A}_n} \Big(S - \mathrm{Diam}\left(J_\alpha\right)\Big) = 0. \tag{3.3}$$

A sufficient but not necessary condition that implies (3.3)*, and is often more convenient, is*

$$\sum_n \max_{\alpha\in\mathcal{A}_n} r_\alpha < \infty. \tag{3.4}$$

Proof. Lemma 3.8 shows that the condition (3.2) on the r_α is equivalent to compatibility of the sequence of resistance forms, which is necessary and sufficient to obtain a resistance form on Ω by Theorems 3.3 and 3.4.

Recall that V_* is $\mathbb{C}$-dense in the complete metric space J, so J is the $\mathbb{C}$-completion of V_*. Similarly, Ω is by definition the R-completion of V_*. Then $\Omega = J$ and the R-topology is the same as the induced $\mathbb{C}$-topology if and only if every $\mathbb{C}$-Cauchy sequence in V_* is R-Cauchy and vice-versa.

Suppose there is an arc-type cell J_α with $r_\alpha = 0$. Then the sequence defined by $x_{2j} = v_{\alpha 1}$ and $x_{2j+1} = v_{\alpha 2}$ is R-Cauchy but not $\mathbb{C}$-Cauchy. Conversely suppose there is a sequence that is R-Cauchy but not $\mathbb{C}$-Cauchy. Compactness of J allows us to select two distinct $\mathbb{C}$-limit points x and y and these will have $R(x,y) = 0$. Then $S(x,y) = 0$ by Lemma 3.7, thus there is a non-trivial path joining x to y such that $r_{\alpha_j} = 0$ for all arc-type cells J_{α_j} on the path. It follows that R-Cauchy sequences are $\mathbb{C}$-Cauchy if and only if $r_\alpha > 0$ for all arc-type cells J_α.

An equivalence class of $\mathbb{C}$-Cauchy sequences is a point $x \in J$, and as noted in Proposition 2.3, x is canonically associated to the nested sequence $\{U_n(x)\}_{n\in\mathbb{N}}$, where $U_n(x)$ is the union of the n-cells containing x. Hence $\mathbb{C}$-Cauchy sequences are R-Cauchy if and only if for each x the resistance diameter of $U_n(x)$ goes to zero when $n \to \infty$. Clearly this is true if

$$\lim_{n\to\infty} \max_{\alpha\in\mathcal{A}_n} \Big(R - \mathrm{Diam}\,\big(J_\alpha\big)\Big) = 0. \tag{3.5}$$

and conversely if (3.5) fails then there is $\epsilon > 0$ and for each n a cell J_α with $|\alpha| = n$ and R-diameter at least ϵ, so compactness of J gives a $\mathbb{C}$-limit point x at which the R-diameter of $U_n(x)$ is bounded below by ϵ independent of n. Applying Lemma 3.7 we then see that $\mathbb{C}$-Cauchy sequences are R-Cauchy if and only if (3.3) holds.

For any cell J_α and any $x \in J_\alpha$ there is a path from $v_{\alpha 1}$ to x which contains at most one arc-type cell of each scale less than $|\alpha|$, so the condition (3.4) implies (3.3). To see this condition is not necessary we consider $\{r_\alpha\}$ as follows. Fix a collection of loop-type cells J_α, one for each scale $|\alpha| \geq 1$, with the property that if J_α is in this collection then no loop-type ancestor of J_α is in the collection. For example the cells with addresses $(3), (13), (113), (1113), \ldots$. If J_α is in this collection set $r_{\alpha 1} = r_{\alpha 2} = |\alpha|^{-1}$. If J_α is a loop-type cell not in this collection set $r_{\alpha 1} = r_{\alpha 2} = 2^{-|\alpha|}$. Also let $r_{\alpha 1} = r_{\alpha 2} = r_a/2$ if J_α is arc-type. For these values r_α we see that any local resistance path contains at most one arc-type cell from this collection, so the S-diameter of a cell of scale $n \geq 2$ is at most $(n-1)^{-1} + 2^{-n-2}$ and (3.3) holds. However $\max_{\alpha\in\mathcal{A}_n} r_\alpha = (n-1)^{-1}$ for each $n \geq 2$, so (3.4) fails. □

Corollary 3.10. *Under the conditions of Theorem 3.9, all the functions in* $\mathrm{dom}(\mathcal{E})$ *are continuous in the topology from* $\mathbb{C}$.

Proof. It follows from (RF4) in Definition 3.1 that functions in $\mathrm{dom}(\mathcal{E})$ are $\frac{1}{2}$-Hölder continuous in the R-topology. □

The n-harmonic functions have a particularly simple form when written with respect to the local resistance metric.

Theorem 3.11. *An n-harmonic function is piecewise linear in the local resistance metric.*

Proof. The complement of V_n is the finite union of cells J_α with $\alpha \in \mathcal{A}_n$. If f is prescribed at $v_{\alpha 1}$ and $v_{\alpha 2}$ then its linear extension to J_α in the local resistance metric has $f(v_{\alpha 3})$ satisfying $r_\alpha f(v_{\alpha 3}) = r_{\alpha 1} f(v_{\alpha 2}) + r_{\alpha 2} f(v_{\alpha 1})$. However the terms in the trace of $\mathcal{E}$ to V_{n+1} that correspond to J_α are

$$r_{\alpha 1}^{-1}\big(f(v_{\alpha 1}) - f(v_{\alpha 3})\big)^2 + r_{\alpha 2}^{-1}\big(f(v_{\alpha 2}) - f(v_{\alpha 3})\big)^2$$

and it is clear this is minimized at precisely the given choice of $f(v_{\alpha 3})$. We have therefore verified that an n-harmonic function extends from V_n to V_{n+1} linearly in the local resistance metric, and the full result follows by induction. □

It is sometimes helpful to think of the local resistance metric as corresponding to a local resistance measure ν, which is defined as follows.

Definition 3.12. The local resistance measure of a compact set E is given by

$$\nu(E) = \inf\Big\{\sum_j r_{\alpha_j} : \bigcup_j J_{\alpha_j} \supset E\Big\}. \tag{3.6}$$

One can easily see that ν has a unique extension to a positive, possibly infinite, Borel measure, and that $S(x, y)$ is the smallest measure of a path from x to y.

This measure has a natural connection to the energy measures corresponding to functions in $\mathrm{dom}(\mathcal{E})$. If $\mathcal{E}$ is local and $f \in \mathrm{dom}(\mathcal{E})$, then the standard way to define the energy measure ν_f is by the formula

$$\int g\, d\nu_f = 2\mathcal{E}(f, fg) - \mathcal{E}(f^2, g)$$

for any bounded quasi-continuous $g \in \mathrm{dom}(\mathcal{E})$, see for instance [6]. If E is open, then another way to define $\nu_f(E)$ is to take the limit defining $\mathcal{E}$ from the resistance form as in Theorem 3.4 and restrict to edges in E. One may informally think of the energy measure $\nu_f(E)$ of a set E as being $\nu_f(E) = \mathcal{E}(f_E)$, where f_E is equal to u on E and zero elsewhere, though this intuition is non-rigorous because f_E may fail to be in the domain of $\mathcal{E}$. If h_m is the piecewise harmonic function equal to u on V_m then $\nu_{h_m} \to \nu_f$, and Theorem 3.11 ensures h_m has constant density $\frac{d\nu_f}{d\nu}$ on every sufficiently small cell. This sequence of piecewise constant densities is bounded by $\mathcal{E}(f)$ in $L^1(d\nu)$, and is a uniformly integrable submartingale. The limit is the density of ν_f with respect to ν, hence all energy measures are absolutely continuous with respect to ν. If we let $\{\Omega_j\}$ be the bounded Fatou components of the polynomial $P(z) = z^2 - 1$ and note that $S(x, y)$ provides a local parametrization of the topological circle $\partial\Omega_j$, then the above argument gives the following description of the resistance form and the energy measures.

Theorem 3.13. *Under the conditions of Theorem 3.9, the domain* $\mathrm{dom}(\mathcal{E})$ *of* $\mathcal{E}$ *consists of all continuous functions such their restriction to each* $\partial\Omega_j$ *is absolutely continuous with respect to the parametrization by the local resistance metric, and the naturally defined derivative* $\frac{df}{dS}$ *is square integrable with respect to* ν*. Moreover, each measure* ν_f *is absolutely continuous with respect to* ν*,*

$$\frac{d\nu_f}{d\nu} = \left(\frac{df}{dS}\right)^2$$

ν-almost everywhere, and

$$\mathcal{E}(f, f) = \sum_{\Omega_j} \int_{\partial\Omega_j} \left(\frac{df}{dS}\right)^2 d\nu.$$

Note that the derivative $\frac{df}{dS}$ can be defined only up to orientation of the boundary components $\partial\Omega_j$, but the densities and integrals in this theorem are independent of this orientation. In general, ν is non-atomic, σ-finite, and for each j we have

$$0 < \nu(\partial\Omega_j) < \infty.$$

It should also be noted that ν plays only an auxiliary role in this theory, and is not essential for the definitions of the energy or the Laplacian.

Two specific choices of ν corresponding to resistance forms of the type described in Theorem 3.9 will be examined in more detail in Sections 5 and 6. In both these cases ν is not finite, but σ-finite.

4. Laplacians on the basilica Julia set

As is usual in analysis on fractals, we use the Dirichlet form to define a weak Laplacian. If μ is a finite Borel measure on J, then the Laplacian with boundary behavior B is defined by

$$\mathcal{E}(f,g) = -\int_J (\Delta_B f) g \, d\mu \quad \text{for all } g \in \mathrm{dom}_B(\mathcal{E}) \tag{4.1}$$

where $\mathrm{dom}_B(\mathcal{E})$ is the subspace of functions in $\mathrm{dom}(\mathcal{E})$ satisfying the boundary condition B. In particular, if there is no boundary condition we have the Neumann Laplacian Δ_N and if the boundary condition is that $g \equiv 0$ on V_0 we obtain the Dirichlet Laplacian Δ_D. We may then define a boundary operator ∂_n^B such that (4.1) can be extended to a general Gauss-Green formula.

$$\mathcal{E}(f,g) = -\int_J (\Delta_B f) g \, d\mu + \sum_{x\in V_0} g(x)\partial_n^B f(x) \quad \text{for all } g \in \mathrm{dom}(\mathcal{E}). \tag{4.2}$$

Proofs of the preceding statements may be found in [12].

The Laplacian may also be realized as a renormalized limit of Laplacians on the graphs G_n by using the method from [11]. For $x \in V_n$ let ψ_x^n denote the unique n-harmonic function with $\psi_x^n(y) = \delta_{x,y}$ for $y \in V_n$, where $\delta_{x,y}$ is Kronecker's delta. Since this function is n-harmonic, $\mathcal{E}(u, \psi_x^n) = \mathcal{E}_n(u, \psi_x^n)$ for all $u \in \mathrm{dom}(\mathcal{E})$. From this and (3.1) we see that if x is in V_{n-1} then

$$\mathcal{E}_n(u, \psi_x^n) = \sum_{y\sim_n x} r_{xy}^{-1}\big(u(x) - u(y)\big),$$

where $y \sim_n x$ indicates that y and x are endpoints of a common arc-type n-cell, and r_{xy} is the resistance of that cell. We may view the expression on the right as giving the value of a Laplacian on G_n at the point x

$$\Delta_n^r u(x) = \sum_{y\sim_n x} r_{xy}^{-1}\big(u(x) - u(y)\big) \tag{4.3}$$

where the superscript r in Δ_n^r indicates its dependence on the resistance form. By the Gauss-Green formula 4.2,

$$\mathcal{E}_n(u, \psi_x^n) = -\int (\Delta u)\psi_x^n \, d\mu$$

so that

$$\Big(\int \psi_x^n \, d\mu\Big)^{-1} \Delta_n^r u(x) = \frac{-\int (\Delta u)\psi_x^n \, d\mu}{\int \psi_x^n \, d\mu} \to -\Delta u(x) \tag{4.4}$$

as $n \to \infty$, which expresses Δ as a limit of the graph Laplacians Δ_n^r, renormalized by the measure μ.

5. Spectral decimation for a self-similar but not conformally invariant Laplacian

The procedure in (4.3) and (4.4) is especially of interest when both the resistance form and the measure have a self-similar scaling that permits us to express Δ_n^r in terms of the usual graph Laplacian

$$\Delta_n u(x) = \sum_{y \sim_n x} \big(u(x) - u(y)\big)$$

and to simplify the expression for the measure. Consider for example the simplest situation, in which a resistance form is constructed on J by setting $r_\alpha = 2^{-|\alpha|}$, where $|\alpha|$ is the length of the word α and using (3.1), and a Dirichlet form is obtained as in Theorem 3.4. We take the measure μ_B to be the natural Bernoulli one in which each n-cell has measure $(4 \cdot 3^{n-1})^{-1}$ for $n \geq 1$. In this case (4.3) simplifies to $\Delta_n^r u(x) = 2^n \Delta_n u(x)$, and since $\int \psi_x^n \, d\mu_B = 2^{-1}3^{-n}$ we may reduce (4.4) to

$$2 \cdot 6^n \Delta_n u(x) \to -\Delta u(x). \tag{5.1}$$

The negative sign occurring on the right of (5.1) is a consequence of the fact that Δ_n is positive definite, whereas the definition (4.1) gives a negative definite Laplacian. The former is more standard on graphs and the latter on fractals.

For the remainder of this section we study the particular Laplacian defined in (5.1) using its graph approximations. We begin by computing the eigenstructure of the graph Laplacian on G_n using the method of spectral decimation (originally from [5, 20, 21], though we follow [1, 15]). The situation may be described as follows. The transition matrix M_n for a simple random walk on G_n is an operator on the space of functions on V_n. If we decompose this space into the direct sum of the functions on V_{n-1} and its orthogonal complement, then M_n has a corresponding block form

$$M_n = \begin{pmatrix} A_n & B_n \\ C_n & D_n \end{pmatrix} \tag{5.2}$$

in which the matrix A_n is a self-map of the space of functions on V_{n-1}. Define the Schur complement S to be $A_n - B_n D_n^{-1} C_n$, and consider the Schur complement of the matrix $M_n - z = M_n - zI$:

$$S_n(z) = A_n - z - B_n(D_n - z)^{-1} C_n. \tag{5.3}$$

If it is possible to solve

$$S_n(z) = \phi_n(z)\Big(M_{n-1} - R_n(z)\Big), \tag{5.4}$$

where $\phi_n(z)$ and $R_n(z)$ are scalar-valued rather than matrix-valued rational functions, then we say that M_n and M_{n-1} are spectrally similar. If we have a sequence $\{M_n\}$ in which each M_n is a probabilistic graph Laplacian on G_n and M_n is spectrally similar to M_{n-1}, then it is possible to compute both the eigenvalues and eigenfunctions of the matrices M_n from $\phi_n(z)$ and $R_n(z)$. Excluding the *exceptional set*, which consists of the eigenvalues of D_n and the poles of $\phi_n(z)$, it may be shown that z is an eigenvalue of M_n if and only if $R_n(z)$ is an eigenvalue of M_{n-1}, and the map $f \mapsto f - (D_n - z)^{-1} C_n f$ takes the eigenspace of M_{n-1} corresponding to $R_n(z)$ bijectively to the eigenspace of M_n corresponding to z ([15, Theorem 3.6]).

Now consider a self-similar random walk on the graph G_n in which the transition probability from $v_{\alpha 3}$ to $v_{\alpha 1}$ in an arc-type cell is a fixed number $p \in (0, 1/2)$. The transition matrix for the cell J_α has the form

$$M = \begin{pmatrix} 1 & 0 & -1 \\ 0 & 1 & -1 \\ -p & -p & 2p \end{pmatrix}. \tag{5.5}$$

The results of [1] imply that the spectral decimation method is applicable to the graph G_n. Moreover, self-similarity implies that both $\phi_n(z)$ and $R_n(z)$ are independent of n and may be calculated by examining a single cell J_α. From (5.5) we see that the eigenfunction extension map is

$$(D - z)^{-1} C = \begin{pmatrix} \frac{p}{2p-z} & \frac{p}{2p-z}, \end{pmatrix}$$

meaning that the value at $v_{\alpha 3}$ of a $\Delta_{|\alpha|+1}$ eigenfunction is $\frac{p}{2p-z}$ times the sum of the values at $v_{\alpha 1}$ and $v_{\alpha 2}$. Since M_{n-1} on a single cell is simply

$$M_0 = \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix},$$

we find that

$$\phi(z) = \frac{p}{2p - z}, \quad \text{and}$$
$$R(z) = \frac{2p+1}{p} z - \frac{1}{p} z^2. \tag{5.6}$$

The exceptional set is exactly the point $\{2p\}$. If we choose the initial Laplacian on G_0 to be

$$\Delta_0 = \begin{pmatrix} q & -q \\ -q & q \end{pmatrix}$$

for some $0 < q < 1$ then we can apply Proposition 4.1 and Theorem 4 of [1] to compute both the multiplicities and the eigenprojectors.

Theorem 5.1. *The eigenvalues of the Laplacian Δ_n on G_n are given by*

$$\sigma(\Delta_0) = \{0, 2q\},$$

$$\sigma(\Delta_n) = \left(\bigcup_{m=0}^{n-1} R^{-m}\{2p\} \right) \bigcup \left(R^{-n}\{0, 2q\} \right).$$

Moreover, if $z \in R^{-n}\{0, 2q\}$ then $\mathrm{mult}_n(z) = 1$ and the corresponding eigenfunctions have support equal to J; if $z \in R^{-m}\{2p\}$ then $\mathrm{mult}_n(z) = 2 \cdot 3^{n-m-1}$ and the corresponding eigenfunctions vanish on V_{n-m-1}.

Proof. For $z \in R^{-n}\{0, 2q\}$ the result follows from Proposition 4.1(i) and Theorem 4(i) of [1]. For $z \in R^{-m}\{2p\}$ the result follows from Proposition 4.1(iii) and Theorem 4(iii) of [1]. In particular,

$$\mathrm{mult}_n(2p) = 4 \cdot 3^{n-1} - |V_{n-1}| + \mathrm{mult}_{n-1}(R(2p)),$$

where $R(2p) = 2$, which is not in the spectrum of any Δ_k, and $|V_k| = 2 \cdot 3^k$. □

Corollary 5.2. *The normalized limiting distribution of eigenvalues (also called the integrated density of states) is a pure point measure κ with atoms at each point of the set*

$$\bigcup_{m=0}^{\infty} R^{-m}\{2p\},$$

Moreover, if $z \in R^{-m}\{2p\}$ then $\kappa(\{z\}) = 2 \cdot 3^{-m-1}$. There is one atom in each gap of the Julia set of R.

A special case occurs if we make the convention that every edge can be traveled in both directions with equal probability, in which case each of the G_n is a regular graph of degree 4. This simple random walk has $p = q = \frac{1}{4}$ from which $R(z) = 6z - 4z^2$. Since our graphs have $2 \cdot 3^n$ vertices, we conclude that in this case the spectral dimension of the corresponding infinite graphs is

$$d_s = \frac{2 \log 3}{\log 6}.$$

One may also consider weighted Laplacians on the infinite graphs by varying the parameter p.

We saw at the end of Section 4 that the Laplacian Δ on the fractal J may be obtained as a limit of graph Laplacians Δ_n, provided that both the Dirichlet form and the measure have self-similar scaling. Under these circumstances, the spectral decimation method gives a natural algorithm for constructing

eigenfunctions of the Laplacian on the fractal. This method was first developed for the Sierpinski Gasket fractal [20, 21, 5].

We illustrate this method for the special self-similar case where the resistance form on J satisfies (3.1) with

$$r_\alpha = 2^{-|\alpha|},$$

where $|\alpha|$ is the length of the word α, and the Dirichlet form is obtained using Theorem 3.4. In this case

$$\mathcal{E}_n(u, \psi^n_x) = \sum_{y\sim_n x} r_{xy}^{-1}\big(u(x) - u(y)\big) = 2^n \sum_{y\sim_n x} \big(u(x) - u(y)\big) = 4 \cdot 2^n \Delta_n u(x)$$

where Δ_n is the graph Laplacian on G_n with equal weight $\frac{1}{4}$ on each edge. This is equivalent to setting $p = q = \frac{1}{4}$. Correcting for the extra factor of $\frac{1}{4}$ in the graph Laplacian we find from (5.1)

$$8 \cdot 6^n \Delta_n u(x) \to -\Delta u(x). \tag{5.7}$$

Here we take that the measure μ in (4.1) is the the natural Bernoulli measure μ_B for which each n-cell has μ_B-measure equal to $(4 \cdot 3^{n-1})^{-1}$ for $n \geq 1$.

Now suppose that $\{u_n\}$ is a sequence of eigenfunctions of Δ_n with eigenvalues λ_n, and the property that $u_n = u_m$ on V_m for $m \leq n$. Further assume that $6^n\lambda_n$ converges and that the function u defined on V_* by $u(x) = u_n(x)$ for $x \in V_n$ is uniformly continuous, and thus can be extended continuously to J. Then (5.7) implies that u is a Laplacian eigenfunction on J with eigenvalue $\lambda = -8 \lim 6^n\lambda_n$. From the formula (5.6) for R we have

$$\lambda_n = \frac{3 + \epsilon_n\sqrt{9 - 4\lambda_{n-1}}}{4}$$

where ϵ_n is one of ± 1 for each n. If only finitely many ϵ_n equal $+1$ then $6^n\lambda_n$ converges and it is easily verified that u is uniformly continuous on V_*, so this method constructs a large number of eigenfunctions. It is actually the case that it constructs all eigenfunctions, though we will only show this for the Dirichlet Laplacian.

The Dirichlet eigenfunctions corresponding to $R^{-m}(2p) = R^{-m}(\frac{1}{2})$ produce Dirichlet eigenfunctions on J. Via an argument from [5], this provides a precise description of the spectrum of the Dirichlet Laplacian Δ_D. Let $\psi(x) = \frac{3-\sqrt{9-4x}}{4}$ and

$$\Psi(x) = \lim_{n\to\infty} 6^n \psi^n(x)$$

in which the limit is well-defined on a neighborhood of zero by the Koenig's linearization theorem (see [16]). Note that $\Psi(0) = 0$ and $\Psi'(0) = 1$, so that Ψ is also invertible on a neighborhood of 0. In the above construction of Dirichlet eigenvalues we asked that all but finitely many of the inverse branches of R be exactly ψ, so that for any such $\lambda = -8 \lim 6^n\lambda_n$ there is n_0 such that $\lambda_{n+1} = \psi(\lambda_n)$ for all $n \geq n_0$. It follows that

$$\lambda = -8 \cdot \lim_{n\to\infty} 6^{n_0} 6^{n-n_0} \psi^{n-n_0}(\lambda_{n_0}) = -8 \cdot 6^{n_0} \Psi(\lambda_{n_0})$$

where $\lambda_{n_0} = R^{-m}\left(\frac{1}{2}\right)$ for some $0 \le m \le n_0$.

Theorem 5.3. *The spectrum of Δ_D on J consists of isolated eigenvalues*

$$\lambda = -8 \cdot 6^{n_0} \Psi\big(R^{-m}(\frac{1}{2})\big)$$

with multiplicity $2 \cdot 3^{n_0-m-1}$, for each $n_0 \ge 1$ and $0 \le m \le n_0$. The corresponding eigenfunctions are those obtained from the eigenfunctions in Theorem 5.1 by spectral decimation.

Proof. Kigami [12] proves that there is a Green's operator with a kernel that is uniformly Lipschitz in the resistance metric, hence the resolvent of the Laplacian is compact and the spectrum of the Laplacian is discrete (pure point with isolated eigenvalues of finite multiplicity accumulating to infinity). Since Δ_D is negative definite, the spectrum consists of a decreasing sequence λ_j of negative real eigenvalues that accumulate only at $-\infty$.

We have seen that the spectral decimation construction produces some Dirichlet eigenvalues and their eigenfunctions. The standard way to determine that all points in the spectrum arise in this manner is a counting argument due to Fukushima and Shima [5]. As the argument holds essentially without alteration, we only sketch the details.

Expanding the Green's kernel $g(x, y)$ of the Laplacian as an L^2-series in the eigenfunctions, we find that

$$-\int g(x,x) d\mu_B(x) = \sum_i \frac{1}{\lambda_i}$$

where the sum is over the eigenvalues of Δ_D, each repeated according to its multiplicity. Similarly, if we let g_m be the Green's kernel for $-8 \cdot 6^m \Delta_m$ and let μ_m be the measure with equal mass at each point of V_m, then

$$-\int g_m(x,x) d\mu_m(x) = \sum_j \frac{1}{\kappa_j^{(m)}}$$

where the sum is over its eigenvalues. However g is continuous and equal to g_m on V_m, and the measures μ_m converge weak* to μ_B, so as $m \to \infty$ the sum of all $\frac{1}{\kappa_j^{(m)}}$ converges to the sum of $\frac{1}{\lambda_i}$.

Now each $\kappa_j^{(m)}$ is $-8 \cdot 6^m \lambda_j^{(m)}$, where $\lambda_j^{(m)} \in R^{-m}(\frac{1}{2})$, and any sequence $-8 \cdot 6^m \lambda_j^{(m)}$ satisfying the conditions of the spectral decimation algorithm converges to some eigenvalue λ_i of Δ_D. With a little care it is possible to show that $\sum_j \frac{1}{\kappa_j^{(m)}}$ converges to the sum $\sum_k \frac{1}{\lambda_{i_k}}$, over those eigenvalues that arise from the spectral decimation. Since $\sum_j \frac{1}{\kappa_j^{(m)}}$ also converges to $\frac{1}{\lambda_i}$, we conclude that the spectral decimation produces all eigenvalues. □

It is worth noting that eigenfunctions also have a self-similar scaling property. Specifically, let f_α denote the natural map from $J_{(1)}$ to J_α if J_α is an

arc-type cell, and from $J_{(3)}$ to J_α if J_α is a loop-type cell. This natural map is defined in the obvious way on the boundary points and then inductively extended to map $V_n \cap J_{(1)}$ to $V_{n+|\alpha|-1} \cap J_\alpha$ (respectively $V_n \cap J_{(3)}$ to $V_{n+|\alpha|-1} \cap J_\alpha$) for each n, whereupon it is defined on the entire cell by continuity. By the definition of the Dirichlet form, this composition scales energy by $2^{1-|\alpha|}$, and by (5.1) it scales the Laplacian by $6^{1-|\alpha|}$. More precisely, if u is such that $(\Delta - \lambda)u = 0$ then $\Delta(u \circ f_\alpha) = 6^{1-|\alpha|}(\Delta u) \circ f_\alpha$, so $\Delta(u \circ f_\alpha)$ is a Laplacian eigenfunction with eigenvalue $6^{1-|\alpha|}\lambda$.

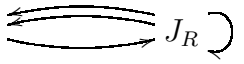
The scaling property provides a very simple description of the Dirichlet eigenfunctions. Suppose u is a Dirichlet eigenfunction obtained as the limit of u_n according to the spectral decimation, and let m be the scale with $\lambda_m = \frac{1}{2}$. Then u_m vanishes on V_{m-1}, so if $|\alpha| = m$ then $u_m \circ f_\alpha$ is a Dirichlet eigenfunction on $J_{(1)}$ (or $J_{(3)}$) with eigenvalue 6^{1-m}. There is a one dimensional space of such functions (note that whether the function is on $J_{(1)}$ or $J_{(3)}$ is immaterial because it vanishes on the boundary), spanned by the Dirichlet eigenfunction on $J_{(1)}$ with value 1 at v_{13}. It follows that the Dirichlet eigenfunctions are all built by gluing together multiples of this function on individual cells of a fixed scale m, subject only to the condition that the values on V_m give a graph eigenfunction with eigenvalue $\frac{1}{2}$.

6. Conformally invariant resistance form and Laplacian

In this section we decompose J as a union of a left and right piece $J = J_L \cup J_R$, where

$$J_L = J \cap \{z : Re(z) \leqslant \tfrac{1-\sqrt{5}}{2}\} = J_{(3)}$$
$$J_R = J \cap \{z : Re(z) \geqslant \tfrac{1-\sqrt{5}}{2}\} = J_{(1)} \cup J_{(2)} \cup J_{(4)}.$$

The sets meet at $a = \frac{1-\sqrt{5}}{2}$, which is the fixed point of $P(z) = z^2 - 1$. The polynomial $P(z)$ maps J_L onto J_R by an one-to-one mapping, and the piece $J_{(4)} \subset J_R$ onto J_R by a one-to-one mapping. It also maps the central part $J_{(1)} \cup J_{(2)}$ of J_R onto J_L by a two-to-one mapping. Therefore the following directed graph



corresponds to the action of $P(z)$, and defines a graph directed cell structure on J. Note that $V_* = \cup_m P^{-m}\{a\}$ and that the preimages of arc-type cells under P are also arc-type cells, while the preimages of loop-type cells are loop-type cells except in the case of $J_{(3)} = J_L$ for which the preimages are $J_{(1)}$ and $J_{(2)}$. This construction is related to group-theoretic results about these graphs and [17, 18, and references therein], and in particular to the substitution scheme in Figures 6 and 7, in which the labeling of components is $J_L = A$ and $J_R = B$.

As usual, we are interested in Dirichlet forms and measures that have a self-similar scaling under natural maps of the fractal. In this case, the mapping

properties described above show that if $\mathcal{E}$ is a Dirichlet form on J then we may define Dirichlet forms $\mathcal{E}^i$ on the cells $J_{(i)}$, $i = 1, 2, 3, 4$ by setting

$$\mathcal{E}^i(u) = \mathcal{E}(u \circ P) \quad \text{for } u \text{ on } J_{(i)} \text{ with } u \circ P \in \mathrm{dom}(\mathcal{E})$$

where $u \circ P$ is taken to be zero off $P(J_{(i)})$ in each case. The form $\mathcal{E}$ is then self-similar under the action of P if for $u \in \mathrm{dom}(\mathcal{E})$

$$\mathcal{E}(u) = \rho \sum_i \mathcal{E}^i\Big(u|_{J_{(i)}}\Big) \tag{6.1}$$

for some ρ.

Theorem 6.1. *Among the resistance forms identified in Theorem 3.9 there is one that has a self-similar scaling under the action of $P(z)$ and is symmetric under complex conjugation. It is unique up to a scalar multiple, and has scaling factor $\rho = \sqrt{2}$.*

Proof. By Theorems 3.3 and 3.4 a necessary and sufficient condition for (6.1) to be true is that the trace of both $\mathcal{E}$ and $\sum_i \mathcal{E}^i$ to V_m are equal for each m. The trace of $\mathcal{E}$ to V_m is a resistance form

$$\mathcal{E}_m(u) = \sum_{\alpha \in \mathcal{A}_m} r_\alpha^{-1}\big(u(v_{\alpha 1}) - u(v_{\alpha 2})\big)^2$$

as in (3.1). The trace of $\sum_i \mathcal{E}^i$ to V_m is found by minimizing the energy when values on V_m are fixed, and each $\mathcal{E}^i$ may be minimized separately. Thus for each i the restriction of u to $J_{(i)}$ has the property that $u \circ P$ is energy minimizing on $P(J_{(i)})$. The result is therefore a resistance form in which the resistance across an arc-type cell J_α is equal to the resistance of the form $\mathcal{E}$ across $P(J_{(\alpha)})$.

We conclude that (6.1) is true if and only if $\mathcal{E}$ is the limit of resistance forms $\mathcal{E}_m$ with $r_{P(J_{(\alpha)})} = \rho r_{J_{(\alpha)}}$. There is only one value of ρ for which this can be satisfied. To see this, note that P^2 maps both $J_{(11)}$ and $J_{(22)}$ to $J_{(1)}$, and both $J_{(12)}$ and $J_{(21)}$ to $J_{(2)}$, so $r_{(11)} = r_{(22)} = \rho^{-2} r_{(1)}$ and $r_{(12)} = r_{(21)} = \rho^{-2} r_{(2)}$. However $r_{(11)} + r_{(12)} = r_{(1)}$ and $r_{(21)} + r_{(22)} = r_{(2)}$, so $r_{(1)} = r_{(2)}$ and $\rho^2 = 2$. Also $r_{(i1)}$ and $r_{(i2)}$ are equal to $\frac{1}{2} r_{(1)}$ for $i = 1, 2$.

Observe that for any arc-type cell $J_{(\alpha)}$ there is a unique $m = m(\alpha)$ so $P^m(J_{(\alpha)}) = J_{(i)}$ for one of $i = 1, 2$. According to our reasoning thus far, we must have $r_{(1)} = r_{(2)}$ and $r_\alpha = 2^{-m(\alpha)/2} r_{(1)}$. It remains to be seen that these resistances satisfy the conditions of Theorem 3.9. The condition $\lim_{|\alpha| \to \infty} r_\alpha = 0$ is immediate, and one can easily verify (3.3), in particular by the computation in Theorem 6.2. For any α we have $P^{m(\alpha)}\big(J_{(\alpha 1)}\big)$ and $P^{m(\alpha)}\big(J_{(\alpha 2)}\big)$ are $J_{(i1)}$ and $J_{(i2)}$ for one of $i = 1, 2$, so the second condition $r_{\alpha 1} + r_{\alpha 2} = r_\alpha$ is equivalent to $r_{11} + r_{12} = r_1$, and the latter has already been established. □

Recall that we have a local resistance metric and a measure $d\nu$ (see Definition 3.6, (3.6) and Theorem 3.13) corresponding to a sequence of resistance forms. For the resistance form from Theorem 6.1 the measure $d\nu$ is related

to the harmonic measure on Fatou components. In this case the measure is infinite. It is well known that in our situation each Fatou component $\Omega \subset \mathbb{C}$ is a topological disc with locally-connected boundary, so the Riemann map σ from the unit disc to Ω has a continuous extension to the unit circle. The harmonic measure from the point $x \in \Omega$ is the image on $\partial\Omega$ of the Lebesgue measure on the circle under the Riemann map with $0 \mapsto x$. It is the same as the exit probability measure for a Brownian motion in Ω started at x, and is the representing measure for the linear functional on $C(\partial\Omega)$ that takes f to the value of the harmonic extension of f at x.

Theorem 6.2. *Let $d\nu$ be the measure corresponding to the unique resistance form from Theorem 6.1 with normalization $r_{(1)} = \frac{1}{2}$. Then ν is an infinite measure that has the self-similar scaling $\nu(P(E)) = \sqrt{2}\nu(E)$ for any set E on which P is injective.*

Let $\Omega = \Omega_0$ be the Fatou component of P that contains the critical point 0, and for each other bounded component Ω_j of the Fatou set of P let m_j be the unique number such that P^{m_j} maps Ω_j bijectively to Ω. Let $d\nu_j$ be the harmonic measure on $\partial\Omega_j$ from the point $P^{-m_j}(0) \in \Omega_j$. Then

$$d\nu = \sum_{j=0}^{\infty} 2^{-m_j/2} d\nu_j$$

Proof. Let σ be a Riemann map from the unit disc to Ω with $\sigma(0) = 0$. Since P^2 is a two-to-one map of Ω onto itself, $\sigma^{-1} \circ P^2 \circ \sigma$ is a two-to-one map of the unit disc onto itself. A version of the Schwartz lemma (for example, that in [19]) implies that $\sigma^{-1} \circ P^2 \circ \sigma = cz^2$, where c is a constant with $|c| = 1$. Moreover, there is a unique σ such that $\sigma(1) = a$, and so $\sigma^{-1} \circ P^2 \circ \sigma = z^2$. Since Ω is locally connected the Riemann map extends to the boundary. Pulling back the measure $d\nu$ to the circle via σ gives a Borel measure that scales by 2 under $z \mapsto z^2$. Consider the set of 2^m preimages of a under the composition power P^{2m} that lie in $\partial\Omega$. These preimages divide $\nu\big|_{\partial\Omega}$ into 2^m equal parts. The preimages of these 2^m points under σ are binary rational points on the unit circle that divide the Lebesgue measure into 2^m equal parts. It follows that $d\nu$ is a multiple of the harmonic measure for the point $\sigma(0) = 0$, and since they both have measure 1 they are equal. A similar alternative construction is to consider an "internal ray" which is the intersection of the negative real half-line with Ω, and its preimages. Then the harmonic measure can be determined in the usual way by computing angles between these rays.

The bounded Fatou components of P are Ω and the topological discs enclosed by loop-type cells. The argument we have just given applies to any such component Ω_j, except that the Riemann map is $P^{-m_j} \circ \sigma$, so $d\nu\big|_{\Omega_j}$ is a multiple of the harmonic measure $d\nu_j$ from the point $P^{-m_j}(0)$. The result then follows from the proof of Theorem 6.1, where it is determined that $\nu(\partial\Omega_j) = 2^{-m_j/2}$. □

It is natural to compare this to other measures on J. We saw in Theorem 3.13 that the energy measures are absolutely continuous to $d\nu$. Another standard measure to consider is the unique balanced invariant probability measure of P, denoted μ_P. It can be obtained, for instance, as the weak limit of the sequence of probability measures μ_m, where each μ_m is 2^{-m} times the counting measure on the 2^m preimages of a. An alternative construction of μ_P defines it as the harmonic measure from infinity, which also can be determined in the usual way by computing angles between the external rays. This measure is a Bernoulli-type measure that has the self-similar scaling $\mu_P(P(E)) = 2\mu_P(E)$ for any set E on which P is injective (or any set if we incorporate multiplicity). The measures μ_P and ν are singular, as may be verified directly by comparing μ_P to ν. Indeed, μ_P has measure 2^{-m} on the preimages $P^{-m}(J_{(i)})$, $i = 1, 2$ whereas $\nu(P^{-m}(J_{(i)})) = 2^{-m/2}$.

Let Δ_P be the Laplacian corresponding to the unique conformally invariant $\mathcal{E}$ and the balanced invariant measure μ_P. Because of Theorem 6.1, Δ_P is (up to a constant multiple) the only Laplacian that has self-similar scaling under the action of $P(z) = z^2 - 1$, and its scaling factor is $2\sqrt{2}$.

Theorem 6.3. *The spectral dimension of Δ_P is equal to* $\dfrac{4}{3}$.

Proof. Since J has graph-directed fractal structure, the method of [9, 14] is applicable. This reduces the spectral dimension computation to finding s such that the spectral radius of the matrix

$$\left(2\sqrt{2}\right)^{-s} \begin{bmatrix} 0 & 2 \\ 1 & 1 \end{bmatrix}$$

is equal to one. Thus $s = \frac{2}{3}$ and $d_s = 2s = \frac{4}{3}$. □
